Title of the circuit: Cyclic Redundancy Check (7, 4) Decoder Circuit for Serial Data

Theory/Description:

In this circuit, a CRC (Cyclic Redundancy Check) decoder has been simulated, with data word size (k) = 4 bits, and code word size (n) = 7 bits. This circuit can be used to decode serially generated 4-bit data after transmitting it over an error prone channel. At the sender side, the data word has to be encoded to detect any errors occurred during the transmission. On both sender and receiver sides, a common divisor of size $(n-k+1) = 4$ bits is used for encoding and decoding.

On the receiver side, the decoder generates a syndrome (remainder) of size $(n-k) = 3$ bits, from the received code word. If this syndrome is zero, no error is detected in the received code word and the extracted data word is accepted, otherwise error is detected and the extracted data word is discarded. The extracted data word is essentially the first four bits of the code word, starting from MSB.

In this decoder, the syndrome is generated using a shift register with three D flip-flops. The 7-bit code word is entered serially. Let this input be called 'serial_in'. Let the outputs of the first to last flip-flops be rm_0 to rm_2 , which are the syndrome (remainder) bits. Let the divisor bits be dv_3 , dv_2 , dv_1 and dv_0 , where dv_3 will always be 1. Now the states of the flip-flops – rm_2 , rm_1 and rm_0 – can be defined for each clock cycle by the following equations, where '&' implies the AND operation, and '^' implies the XOR operation:

- $rm_0(t+1) = [rm_2(t) \& dv_0(t)] \wedge serial_in(t)$
- $rm_1(t+1) = [rm_2(t) \& dv_1(t)] \wedge rm_0(t)$
- $rm_2(t+1) = [rm_2(t) \& dv_2(t)] \wedge rm_1(t)$

At the 7th posedge of the clock, if all the syndrome bits are 0, the 'accept' bit is 1, otherwise it is 0, so we use a 3-input NOR gate. This NOR output undergoes the AND operation with a

square pulse, which is 0 until the 7th posedge, and 1 for the next clock cycle, so that the 'accept' bit can be 1 only in the 7th cycle.

This method is illustrated in Figures 1 and 2. The code words for the two cases are 1001_110 and 1000_110, and the divisor is 1011, same as that in the encoder. The 3-bit remainders in both the cases are called syndromes. In case 1, since the syndrome is 000, the extracted data word is accepted, while in case 2 it is discarded, since the syndrome is not 000.

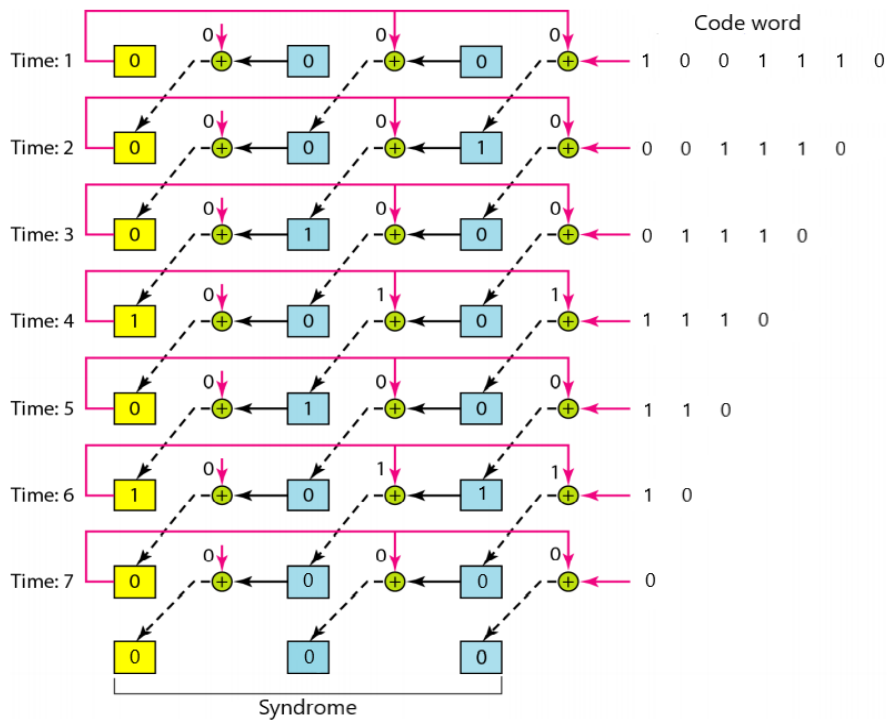

Figure 2: CRC (7, 4) Decoding with Serial Input – Working of the Circuit

Figure 3 shows the codebook for all possible 4-bit data words. Since the minimum Hamming distance between any two code words is 3, this technique can detect errors of up to 2 bits.

<i>Dataword</i>	<i>Codeword</i>	<i>Dataword</i>	<i>Codeword</i>
0000	0000000	1000	1000101
0001	0001011	1001	1001110
0010	0010110	1010	1010011
0011	0011101	1011	1011000
0100	0100111	1100	1100010
0101	0101100	1101	1101001
0110	0110001	1110	1110100
0111	0111010	1111	1111111

Results (Input, Output waveforms):

The working of the circuit in Figures 1 and 2 has been demonstrated in the following results. Both the cases in Figure 1 have been simulated. The divisor bits dv_2 , dv_1 and dv_0 have been set to 0V, 5V and 5V respectively, so that the divisor becomes 1011. A reset pulse for the first 5 seconds is used to reset the flip-flops initially. The clock signal is a square wave of period 20s with a 50% duty cycle. The signals 'serial_in' are the serial input code words 1001_110 and 1000_110. The syndrome bits obtained from the outputs of the flip-flops undergo the NOR operation. The final 'accept' bit is obtained at the rising edge of the 7th clock pulse, i.e., at the 130th second. This can be sampled anytime from 130 to 150 seconds. The syndrome bits for case 1 at each clock cycle can be verified from Figure 2, and the 'accept' bit after the 7th posedge can be verified for both cases from Figure 1.
